

## Authors' response

### RC1 (Anonymous referee)

---

**1.** Obviously, the authors have made an effort to maximize the efficiency of the hetero-nuclear decoupling by expanding the original 16 step supercycle to 64 steps and by applying a very high RF field strength of 24 kHz, covering the bandwidth in excess of 60 kHz (4000 ppm at 0.33 T, 14 MHz <sup>1</sup>H). Since the CH proton chemical shift range at this field strength is less than 42 Hz (3 ppm) perhaps a simple CW decoupling would have been more efficient. It would also offer means of altering the size of the effective hetero-nuclear coupling.

**Response:** The homogeneity of 0.33 T region of 2F NMR spectrometer is about 10 ppm, which is much worse than that typical for high-field NMR instruments (for example, the homogeneity of 14.1 T main field is about 0.05 ppm). To make sure that the <sup>1</sup>H-<sup>13</sup>C interactions are suppressed in the entire sample volume the bandwidth of composite decoupling was increased. The broadband decoupling method used here required only 0.5 W RF power at 14 MHz; thus, it does not impose any problems such as sample heating.

**Changes made:** clarifying statements are added.

**2.** Introduction: when describing slow and fast passage through the LAC the authors should indicate the time scale that is used to define what is fast and what is slow. I would guess it is the J-coupling (H-C, C-C, multiplet structure, etc.) that defines the desired time scale. Please clarify.

**Response:** We have added clarifying sentences, explicitly introducing the adiabaticity parameter.

**3.** Page 3, section B, lines 2 and 3: the proton resonance frequency is provided for the 14.1 T field, but not for the more unusual 0.33 T field. Please correct.

**Response:** Done

**4.** Page 3, section B, paragraph 2: the authors use RE-BURP refocusing pulse for inversion - nothing wrong with that, except the reader might be curious about the selection of the pulse shape, e.g. why not use an inversion pulse, such as I-BURP or G3?

**Response:** The use of RE-BURP has no strict prerequisites. However, RE-BURP is a general-rotation 180° pulse which is less sensitive to the initial nuclear magnetization state than I-BURP ([https://doi.org/10.1016/0022-2364\(91\)90034-Q](https://doi.org/10.1016/0022-2364(91)90034-Q)) and has narrower excitation profile in comparison with G3.

**Changes made:** clarifying statement is added.

**5.** Page 3, line 112: "WALTZ-64 supercycle" should be "WALTZ decoupling with MLEV-64 supercycle". A reference to MLEV-64 should be given along with that for the WALTZ decoupling.

**Response:** Done

**6.** Caption to Figure 2: the RF field strength for the 0.56 W decoupling at B(HF) should be given.

**Response:** Done

**7.** Page 11, lines 346-348, the last statement before the section V (Conclusions): please indicate that this statement is for abundant (or labelled) spins only.

**Response:** We have added a clarifying statement just before the conclusions.

## RC2 (Stephan Appelt)

---

**2a:** A small confusion arises due to Figure 1, where the  $^{13}\text{C}$  spectrum from L-leucine measured at 100.62 MHz is shown. Later in Figure 5 the  $^{13}\text{C}$  spectra is presented at 150.9 MHz. The reader will ask why the  $^{13}\text{C}$  NMR spectrum has not been measured at 150,9 MHz?

**Response:** The  $^{13}\text{C}$  spectrum of L-leucine was measured both at 100.62 MHz and 150.9 MHz, the resolution of the 100.62 MHz spectrum is better than one of 150.9 MHz.

**Changes made:** Figure 1 was corrected to present 150.9 MHz  $^{13}\text{C}$  spectrum of L-leucine

**2b:** In section B in line 99 an unprecise statement is made “First, a non-equilibrium state is generated at  $B_{\text{HF}}$  by applying a selective pulse”. Please specify here that a selective  $180^\circ$  pulse is applied to  $C^{\text{}}(\delta_2)$ , leading to a non-equilibrium state, i.e into a population inversion (refer here to Figure 2).

**Response:** Done

**2c:** There is an error in the signs in Equation (1), either all signs in the Zeeman terms ( $-\omega_1 I_z - \omega_2 I_z - \omega_3 S_z$ ) are negative or all are positive, but mixed signs cannot be true. Furthermore Equation (1) and (10) are inconsistent with Equation (2), where all signs before  $I_z$  and  $S_z$  are negative

**Response:** Sign error in eqn. (1) is now corrected. We believe that there is no inconsistency between eqn. (10) and eqn. (2).

**2d:** The exact form of  $\omega_1$ ,  $\omega_2$  and  $\omega_3$  should be stated in line 139, i.e.  $\omega_1 = \gamma_C(1+\delta_2) B_{\text{HF}}$ ,  $\omega_2 = \gamma_C(1+\delta_2) B_{\text{HF}}$  and  $\omega_3 = \gamma_H B_{\text{HF}}$ .

**Response:** we introduce  $\omega$ 's explicitly and explain all parameters.

**2e:** The experimental results in Figures 5B and 6B are in good agreement with the theoretical expectation only in the first 10 ms. Especially in Figure 6B the experimental data does not show the oscillating features as suggested by the theory. An explanation for this deviation would be very helpful.

**Response:** In the original version this issue, non-ideal agreement between theory and experiment, has been addressed. We attribute it to two factors: (i) relaxation effects, not taken into account in the simulation, (ii) lack of the precise knowledge of the  $B(t)$  profile. No changes are made in the text, since we do not have any further comments on this.

**3.** Technical corrections, typing errors and references:

**Response:** Changed as requested.

## Comments from Nino Wili

---

**1)** The situation where heteronuclear couplings “quench” the effect of a strong homonuclear coupling appears similar to the origin of the “spin diffusion barrier” in EPR/DNP. In the latter, a difference in hyperfine couplings between protons and an unpaired electron inhibits the efficient polarization transfer between these protons, even if there is a strong homonuclear dipolar coupling between them. Hyperfine decoupling reduces this effect. Some readers with a different background might find it helpful if this similarity is pointed out (if you agree it is there).

**Response:** we agree that there is a similarity of the two phenomena. This analogy is mentioned in the conclusions and a review paper on spin diffusion by Ramanathan is cited.

**2)** I find it a bit awkward to use “surprising” in a title.

**Response:** we decided to make the title a bit “catchy”.

**3)** Eq (1): it seems there should be a minus sign before  $\omega_1$ . Or is it intentionally left out?

**Response:** corrected, this was a typo.

**4)** You give the homonuclear J-couplings in table 1. Could you also give the  $^1\text{H}$ - $^{13}\text{C}$  couplings of the protons that couple to these carbons? Or did I miss them?

**Response:** corrected, direct J(CH) coupling values are also listed in Table 1.

**5)** Related to 4) Would you be willing to share your simulation code? I would be interested to look at the influence of different couplings strengths and field-cycling speeds

**Response:** we can share the code on request.

# Surprising absence of strong homonuclear coupling at low magnetic field explored by two-field NMR spectroscopy

## Abstract

Strong coupling of nuclear spins, which is achieved when their scalar coupling  $2\pi J$  is greater than or comparable to the difference  $\Delta\omega$  in their Larmor precession frequencies in an external magnetic field, gives rise to efficient coherent longitudinal polarization transfer. The strong-coupling regime can be achieved when the external magnetic field is sufficiently low, as  $\Delta\omega$  is reduced proportional to the field strength. In the present work, however, we demonstrate that in heteronuclear spin systems these simple arguments may not hold, since heteronuclear spin-spin interactions alter the  $\Delta\omega$  value. The experimental method that we use is two-field NMR (Nuclear Magnetic Resonance), exploiting sample shuttling between a high field, at which NMR spectra are acquired, and low field, where strong couplings are expected, at which NMR pulses can be applied to affect the spin dynamics. By using this technique, we generate zero-quantum spin coherences by means of non-adiabatic passage through a level anti-crossing and study their evolution at low field. Such zero-quantum coherences mediate the polarization transfer under strong coupling conditions. Experiments performed with an  $^{13}\text{C}$  labelled amino acid clearly show that the coherent polarization transfer at low field is pronounced in the  $^{13}\text{C}$ -spin subsystem under proton decoupling. However, in the absence of proton decoupling, polarization transfer by coherent processes is dramatically reduced, demonstrating that heteronuclear spin-spin interactions suppress the strong coupling regime even when the external field is low. A theoretical model is presented, which can simulate the reported experimental results.

## 35 I. Introduction

36 The topological and conformational information provided by scalar couplings lies at the foundation of the  
37 analytical power of NMR spectroscopy (Ernst et al., 1987; Keeler, 2005; Levitt, 2008; Cavanagh, 2007). The  
38 strong coupling case is encountered when scalar coupling constants are not negligible with respect to the  
39 difference of resonance frequency between the coupled spins (Keeler, 2005). Understanding strong scalar  
40 couplings and their spectral signature was essential when NMR was introduced for chemical analysis,  
41 which was typically performed at magnetic fields considered today as low (Bodenhausen et al., 1977;  
42 Pfändler and Bodenhausen, 1987). Modern high-field NMR is widely based on the exploitation of weak  
43 scalar couplings, so that strong scalar couplings have remained a nuisance, in particular in aromatic spin  
44 systems (Vallurupalli et al., 2007; Foroozandeh et al., 2014). Recently, the development and availability of  
45 benchtop NMR spectrometers operating at low or moderate magnetic fields (Grootveld et al., 2019), has  
46 revived the interest in the understanding of strong scalar couplings in conventional NMR.

47 Contrarily to conventional NMR, NMR at near-zero or ultralow magnetic fields (ZULF-NMR), explores the  
48 benefits of NMR in the strong scalar-coupling regime. At such magnetic fields, typically smaller than 1  $\mu$ T,  
49 scalar coupling interactions dominate all Zeeman interaction and dictate the eigenstates of spin systems  
50 and transition energies obtained in spectra (Ledbetter et al., 2011; Tayler et al., 2017; Blanchard and  
51 Budker, 2016). However, for homonuclear couplings, the transition between the weak- and strong-  
52 coupling regimes occurs in a range of magnetic fields, where the Zeeman interaction is still dominant  
53 (Ivanov et al., 2006; Ivanov et al., 2008; Ivanov et al., 2014; Appelt et al., 2010; Türschmann et al., 2014).  
54 This transition between weak and strong couplings can be investigated by varying the magnetic field  
55 applied to the sample on a high-field magnet, which is usually performed by moving the sample through  
56 the stray field with a shuttle system (Roberts and Redfield, 2004a, b; Redfield, 2012; Wagner et al., 1999;  
57 Bryant and Korb, 2005; Goddard et al., 2007; Chou et al., 2016; Chou et al., 2017; Charlier et al., 2013;  
58 Cousin et al., 2016a; Cousin et al., 2016b; Zhukov et al., 2018; Kiryutin et al., 2016). These studies have  
59 highlighted the effects of level anti-crossings (LACs) (Miesel et al., 2006; Ivanov et al., 2014). When the  
60 passage through a LAC is slow, the transition is adiabatic and the population of eigenstates is smoothly  
61 converted to the new eigenstates. When the transition is fast, coherences can be generated between the  
62 new eigenstates and time-oscillations of the population of high-field eigenstates can be observed  
63 (Pravdivtsev et al., 2013; Kiryutin et al., 2013). This phenomenon has been observed on a variety of  
64 homonuclear spin systems. Heteronuclear scalar couplings have been shown to alter LACs in homonuclear  
65 spin systems (Korchak et al., 2012); yet, the properties of such heteronuclear couplings on LACs are not  
66 fully understood, in particular, in spin systems with extensive networks of homo- and heteronuclear scalar  
67 couplings. As usual, non-adiabatic variation, which gives rise to excitation of coherences, means that the  
68 adiabatic eigenstates of the spin system change with time fast as compared to the rate of internal  
69 evolution of the system. Specifically, for each pair of adiabatic states,  $|i\rangle$  and  $|j\rangle$ , the parameter

$$\xi_{ij} = \frac{\langle j | \frac{d}{dt} | i \rangle}{\omega_{ij}}$$

70  
71 Is much greater than 1 (here  $\omega_{ij}$  is the energy difference between the states, measured in angular  
72 frequency units). When  $\xi_{ij} \ll 1$ , switching is adiabatic and populations follows the time-dependent  
73 eigenstates.

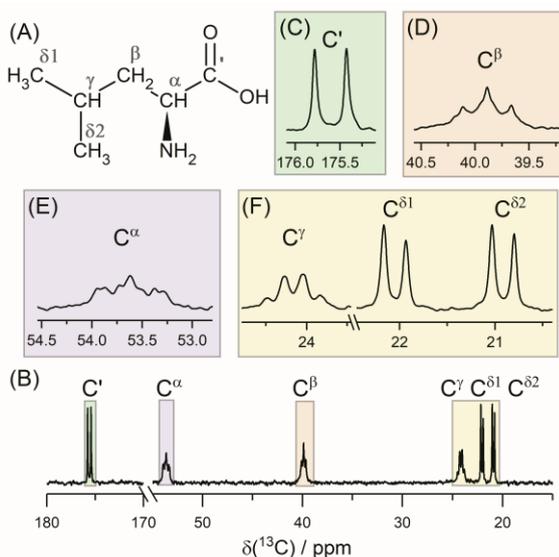

74 Here, we investigate the effect of heteronuclear scalar couplings on LACs in a spin system typical of  
75 biomolecular NMR, a uniformly carbon-13 labeled amino acid (leucine), which combines extensive  
76 networks of homo- and heteronuclear scalar couplings. Essentially, we exploit the ability to apply  
77 composite pulse decoupling on our two-field NMR spectrometer (Cousin et al., 2016a) to switch on and  
78 off heteronuclear scalar couplings at low magnetic field. We demonstrate that heteronuclear scalar  
79 couplings alter LACs by sustaining the weak-coupling regime in a carbon-13 homonuclear spin system.

80 Composite pulse decoupling at low magnetic field restores the strong scalar coupling regime in the  
 81 carbon-13 nuclei of the isopropyl group of leucine at 0.33 T. Our results identify how heteronuclear  
 82 couplings alter homonuclear couplings at low magnetic fields, which could be exploited in low-field NMR  
 83 methodology and may be considered in further developments of total correlation spectroscopy (TOCSY)  
 84 (Braunschweiler and Ernst, 1983) mixing sequences in high-field NMR.

## 85 II. Methods

### 86 A. Sample preparation

87 Experiments have been performed using the following sample: 76 mM 99% enriched  $^{13}\text{C}$ ,  $^{15}\text{N}$  labeled L-  
 88 leucine (Leu) in 90%  $\text{H}_2\text{O}$  10%  $\text{D}_2\text{O}$  solution.  $^{13}\text{C}$ ,  $^{15}\text{N}$  enriched L-leucine were purchased from Sigma-Aldrich  
 89 and used as it stands.  $^{13}\text{C}$ -NMR spectrum of the labelled Leu molecule is shown in **Figure 1**. We also show  
 90 separately the signals of the individual carbon nuclei. Broadband proton decoupling was used to simplify  
 91 the spectrum. Here, we will focus on a three-spin system, formed by the  $\text{C}^\gamma$  and two  $\text{C}^\delta$  nuclei of the  
 92 isopropyl moiety. We will study polarization transfer in this subsystem upon fast switch of the external  
 93 magnetic field obtained by a transfer of the sample though the stray field of a high-field NMR magnet.

94

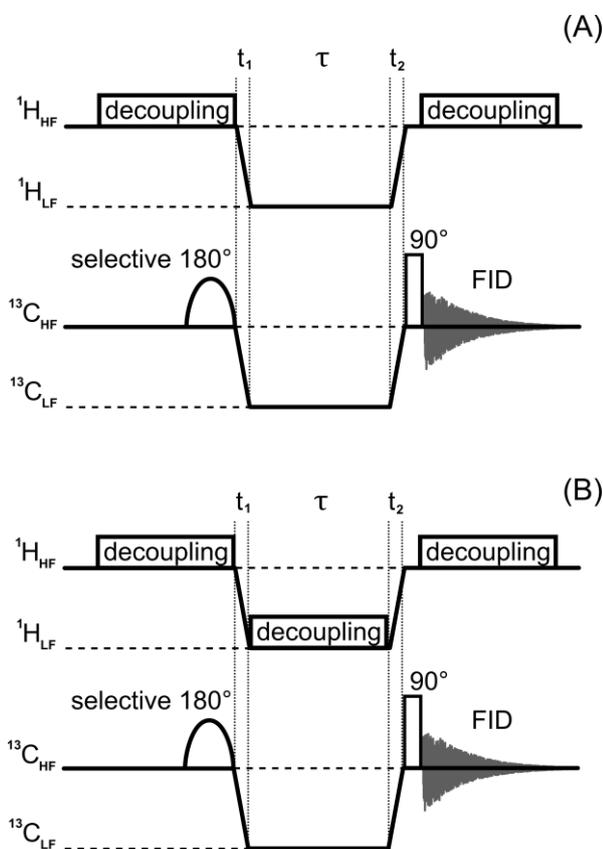

95 **Figure 1**. Structure of  $^{13}\text{C}$ ,  $^{15}\text{N}$  L-leucine **(A)** and 150.9 MHz  $^{13}\text{C}$ -NMR spectrum **(B)** under broadband  $^1\text{H}$  decoupling.  
 96 Signal of each carbon nuclei is also shown separately **(C)-(E)**. The multiplet structure in the spectrum is due to  $^{13}\text{C}$ -  
 97  $^{13}\text{C}$  and  $^{13}\text{C}$ - $^{15}\text{N}$  scalar interactions.

### 98 B. Field-cycling NMR experiments

99 NMR experiments were performed on a two-field NMR spectrometer (Cousin et al., 2016a) with fast  
 100 sample shuttling (Charlier et al., 2013). The high field  $B_{HF} = 14.1$  T is the detection field of a 600 MHz  
 101 NMR spectrometer while the low field is  $B_{LF} = 0.33$  T corresponding to 14 MHz  $^1\text{H}$  NMR frequency. The  
 102 magnetic field in the low-field centre is sufficiently homogeneous (inhomogeneities of the order of 10  
 103 ppm) so that radiofrequency (RF) pulses can be applied by using a triple-resonance NMR probe, as  
 104 described previously (Cousin et al., 2016a).

105 Field-cycling NMR experiments were run according to the pulse sequences depicted in **Figure 2**. First, a  
 106 non-equilibrium state is generated at  $B_{HF}$  by applying a selective  $\pi$  pulse to the  $\text{C}^{\delta 2}$  nucleus (shaped RE-  
 107 BURP pulse (Geen and Freeman, 1991), the pulse duration was 46.4 ms, the peak RF-field amplitude was  
 108 adjusted to cover ca. 100 Hz bandwidth around the center of  $\text{C}^{\delta 2}$  signal). RE-BURP shaped pulse was used  
 109 since it is less sensitive to the initial nuclear magnetization state than I-BURP (Geen and Freeman, 1991)  
 110 and has narrow excitation profile. To improve the selectivity of the pulse, simultaneous proton decoupling  
 111 was used, which reduces multiplet overlap in the carbon-13 NMR spectrum. Following this preparation,

112 the sample was shuttled from the high-field center to the low-field center  $B_{HF} \rightarrow B_{LF}$  with a duration  
 113  $t_1 = 110$  ms. The field jump is fast enough to be non-adiabatic and it is aimed to excite a spin coherence.  
 114 Subsequently, the coherence evolves at  $B_{LF}$  during a variable time period  $\tau$ . The shuttle transfer back to  
 115 the high-field center leads to a second field jump  $B_{LF} \rightarrow B_{HF}$  with a duration  $t_2 = 95$  ms. This second non-  
 116 adiabatic field jump to  $B_{HF}$  converts the coherence into a population difference. Detection is performed  
 117 after a  $\pi/2$  pulse on the carbon-13 channel in the presence of proton decoupling. We perform two types  
 118 of experiments, in which the carbon spin coherence (zero-quantum coherence, ZQC) evolves at  $B_{LF}$  in the  
 119 absence (see **Figure 2A**) and in the presence (see **Figure 2B**) of proton composite-pulse decoupling.  
 120 Decoupling at  $B_{LF}$  has been performed using composite pulse decoupling pulse with the **WALTZ**  
 121 **decoupling with MLEV-64 supercycle** (Shaka et al., 1983; Levitt et al., 1982) at low field on the proton RF-  
 122 channel (operating at 14 MHz corresponding to the proton NMR frequency at 0.33 T). **Composite pulse**  
 123 **decoupling is used because of the rather high inhomogeneity of the  $B_{LF}$  field, which is of the order of 10**  
 124 **ppm: under such conditions continuous-wave decoupling would require higher power, potentially giving**  
 125 **rise to sample heating.** The  $\tau$ -dependence of polarization is expected to be oscillatory, due to the coherent  
 126 polarization exchange within the expectedly strongly coupled system of the  $C^\gamma$  and two  $C^\delta$  carbon-13  
 127 nuclei.

128 **Figure 2.** Experimental protocols of field-cycling NMR experiments without  $^1\text{H}$  decoupling at the low field (A) and  
 129 with  $24$  kHz WALTZ-64  $^1\text{H}$  decoupling at the low field (B). Details of the experiments:  $0.56$  W **10 kHz** WALTZ-64  
 130 composite pulse decoupling on the proton channel was applied at  $B_{HF}$  during  $100$  ms prior to a selective  $180$ -degree  
 131 pulse, in order to enhance  $^{13}\text{C}$  polarization by the nuclear Overhauser effect. The sample shuttle times,  $t_1$  and  $t_2$ ,  
 132 were  $80$  ms and  $120$  ms, respectively. Selective inversion was performed with a ReBURP pulse (Geen and Freeman,  
 133 1991) with a duration of  $46.4$  ms at the  $C^{\delta 2}$  resonant frequency covering *ca.*  $100$  Hz bandwidth. The delay  $\tau$  at low  
 134 field was **incremented** with a  $5$  ms step. After sample transfer to high field, a hard  $90$ -degree pulse generated  $^{13}\text{C}$   
 135 transverse magnetization; FID acquisition was done during  $1.56$  s under  $2.7$  kHz WALTZ-64 proton decoupling.  
 136

### 137 III. Theory

#### 138 A. Polarization transfer in a 3-spin system

139 In this subsection, we provide a theoretical description of the field-cycling NMR experiments. First, we  
 140 present the analytical treatment of polarization transfer among two nuclei of the same kind, here spin  $I_1$   
 141 and spin  $I_2$  (e.g. two carbon-13 nuclei), in the presence of a third spin  $S$ , which can be a heteronucleus  
 142 (e.g. here a proton). This is the minimal system allowing us to detail the effect of a heteronucleus on  
 143 polarization transfer among strongly coupled spins. We assume that spins  $I_1$  and  $I_2$  are in strong coupling  
 144 conditions, meaning that the difference,  $\Delta\omega$ , in their Zeeman interaction frequencies with the external  
 145 field is smaller than or comparable to the scalar-coupling constant,  $2\pi J_{12}$ , between them. When the  
 146 strong coupling regime is achieved, the zero-quantum part of the scalar coupling, given by the operator  
 147  $\{\hat{I}_{1+}\hat{I}_{2-} + \hat{I}_{1-}\hat{I}_{2+}\}$ , becomes active, giving rise to flips and flops of spins  $I_1$  and  $I_2$ . The couplings to the  
 148 third spin  $S$ ,  $J_{13}$  and  $J_{23}$ , are assumed to be unequal (otherwise coupling to the proton gives rise to an  
 149 identical shift of the NMR frequencies of spins 1 and 2 and does not modify the eigenstates of this  
 150 subsystem). The Hamiltonian of the spin system can be written as follows (in  $\hbar$  units):

$$\hat{\mathcal{H}}_{CCH} = \omega_1 \hat{I}_{1z} - \omega_2 \hat{I}_{2z} - \omega_3 \hat{S}_z + 2\pi J_{12} (\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2) + 2\pi J_{13} \hat{I}_{1z} \hat{S}_z + 2\pi J_{23} \hat{I}_{2z} \hat{S}_z \quad (1)$$

151 Here  $\hat{\mathbf{I}}_1$ ,  $\hat{\mathbf{I}}_2$  and  $\hat{\mathbf{S}}$  are the spin operators;  $\omega_1 = \gamma_1(1 + \delta_1)B$ ,  $\omega_2 = \gamma_1(1 + \delta_2)B$  and  $\omega_3 = \gamma_S(1 + \delta_S)B$   
 152 stand for the NMR frequencies of the corresponding nuclei (with  $\gamma_{I,S}$  being the corresponding  
 153 gyromagnetic ratios,  $\delta_i$  being the chemical shifts and  $B$  being the magnetic field strength). We assume  
 154 that the heteronucleus  $S$  is coupled weakly to  $I$  spins due to the large difference in their NMR frequencies,  
 155 i.e.,  $|\omega_1 - \omega_3|, |\omega_2 - \omega_3| \gg |\omega_1 - \omega_2|, 2\pi J_{13}, 2\pi J_{23}$ , and keep only the secular part of the heteronuclear  
 156 coupling Hamiltonian.

157 In the present case, the nuclear magnetic number,  $m_S$ , of spin  $S$  is a “good quantum number”, which is  
 158 conserved because  $\hat{S}_z$  commutes with the Hamiltonian. For this reason, it is possible to find the solution  
 159 for the spin dynamics of spins  $I_1$  and  $I_2$  for two separate cases, which corresponds to the two different  
 160 values of  $m_S$  being  $+\frac{1}{2}$  and  $-\frac{1}{2}$ , i.e., spin  $S$  is in the “spin-up”  $|\alpha\rangle$  state or “spin-down”  $|\beta\rangle$  state. In each  
 161 case, the Hamiltonian of the carbon subsystem is as follows:

$$\hat{\mathcal{H}}_{CC} = -\{\omega_1 - 2\pi J_{13} S_z\} \hat{I}_{1z} - \{\omega_2 - 2\pi J_{23} S_z\} \hat{I}_{2z} + 2\pi J_{12} (\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2) \quad (2)$$

162 Hence, in the Hamiltonian given by eq. (1) we replace the  $\hat{S}_z$  operator by the  $m_S$  value, which is  $\pm \frac{1}{2}$ . Hence,  
 163 the  $\Delta\omega$  value is modified and it depends on the  $m_S$  value:

$$\Delta\omega_{\pm} = \{\omega_1 - \omega_2\} \mp \pi \{J_{13} - J_{23}\} = \Delta\omega \mp \pi \cdot \Delta J \quad (3)$$

164 The eigenstates of the subsystem of spin 1 and spin 2 are

$$\begin{aligned} |1\rangle &= |\alpha\alpha\rangle, \quad |2\rangle_{\pm} = \cos\theta_{\pm} |\alpha\beta\rangle + \sin\theta_{\pm} |\beta\alpha\rangle \\ |3\rangle_{\pm} &= -\sin\theta_{\pm} |\alpha\beta\rangle + \cos\theta_{\pm} |\beta\alpha\rangle, \quad |4\rangle = |\beta\beta\rangle \end{aligned} \quad (4)$$

165 Here the “mixing angle” is given by the values of  $\Delta\omega_{\pm}$  and  $J_{12}$ :  $\tan 2\theta_{\pm} = 2\pi J_{12} / \Delta\omega_{\pm}$ . When  $\Delta\omega_{\pm}$   
 166 approaches zero, the mixing angle goes to  $\frac{\pi}{4}$  meaning that the eigenstates become singlet and triplet  
 167 states: the spins are strongly coupled. When  $\Delta\omega_{\pm}$  is much greater than the coupling, the eigenstates are  
 168 obviously the Zeeman states.

169 Even in this simple system, it is clear that the condition  $|\omega_1 - \omega_2| \ll 2\pi J_{12}$  is not sufficient to guarantee  
 170 strong coupling of the two carbons. Indeed, when  $2\pi \Delta J$  is greater than  $\Delta\omega$  and  $2\pi J_{12}$  the carbon spins  
 171 become weakly coupled in the two sub-ensembles, corresponding to  $m_S = \pm \frac{1}{2}$ .

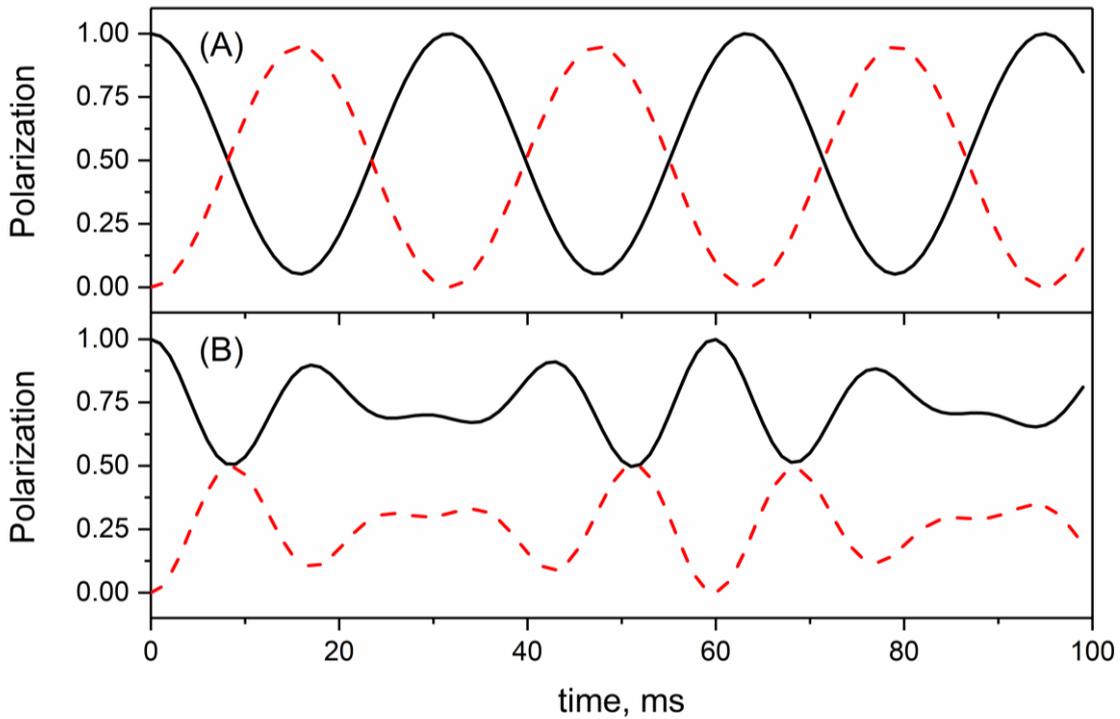

172 How do heteronuclear couplings affect polarization transfer in the carbon system? We assume that at  $t =$   
 173 0 one of the spins has polarization  $\langle I_{1z} \rangle = P_0$  and the other spin is not polarized,  $\langle I_{2z} \rangle = 0$ . Hereafter, it  
 174 is convenient to use normalization  $P_0 = 1$ . The state of the spin system is then given by the density  
 175 operator

$$\sigma_0 = \hat{I}_{1z} \quad (5)$$

176 As shown previously (Ivanov et al., 2006), in the two-spin system of  $I_1$  and  $I_2$ , in the absence of coupling  
177 to any other spin, the polarization evolves with time as follows:

$$\langle I_{1z} \rangle(t) = 1 - \sin^2 \theta \frac{1 - \cos[\omega_{ZQC} t]}{2}, \quad \langle I_{2z} \rangle(t) = \sin^2 \theta \frac{1 - \cos[\omega_{ZQC} t]}{2} \quad (6)$$

178 where  $\tan 2\theta = 2\pi J_{12}/\Delta\omega$  and the oscillation frequency  $\omega_{ZQC} = \sqrt{\Delta\omega^2 + (2\pi J_{12})^2}$  is the frequency of  
179 the ZQC between the eigenstates  $|2\rangle$  and  $|3\rangle$ . Hence, coherent exchange of polarization is taking place.  
180 As  $\Delta\omega$  becomes smaller the frequency of the oscillations decreases, but the amplitude increases: at  $\Delta\omega \rightarrow$   
181  $0$  we obtain  $\omega_{ZQC} = 2\pi|J_{12}|$  and complete exchange is possible when  $t = 1/(2J_{12})$ .

182  
183 **Figure 3.** Polarization transfer among two strongly coupled nuclei (A) in the absence and (B) in the presence (bottom)  
184 of a heteronucleus. Here, we present the time dependence of  $\langle I_{1z} \rangle$  (black solid lines) and  $\langle I_{2z} \rangle$  (red dashed lines),  
185 normalized to the initial value of  $\langle I_{1z} \rangle$ . The density operator at time  $t = 0$  is  $\sigma_0 = \hat{I}_{1z}$ . Parameters of the simulation  
186 were  $\Delta\omega/2\pi = 10$  Hz,  $J_{12} = 30$  Hz, and (a)  $\Delta J = 0$  Hz and (b)  $\Delta J = 100$  Hz.

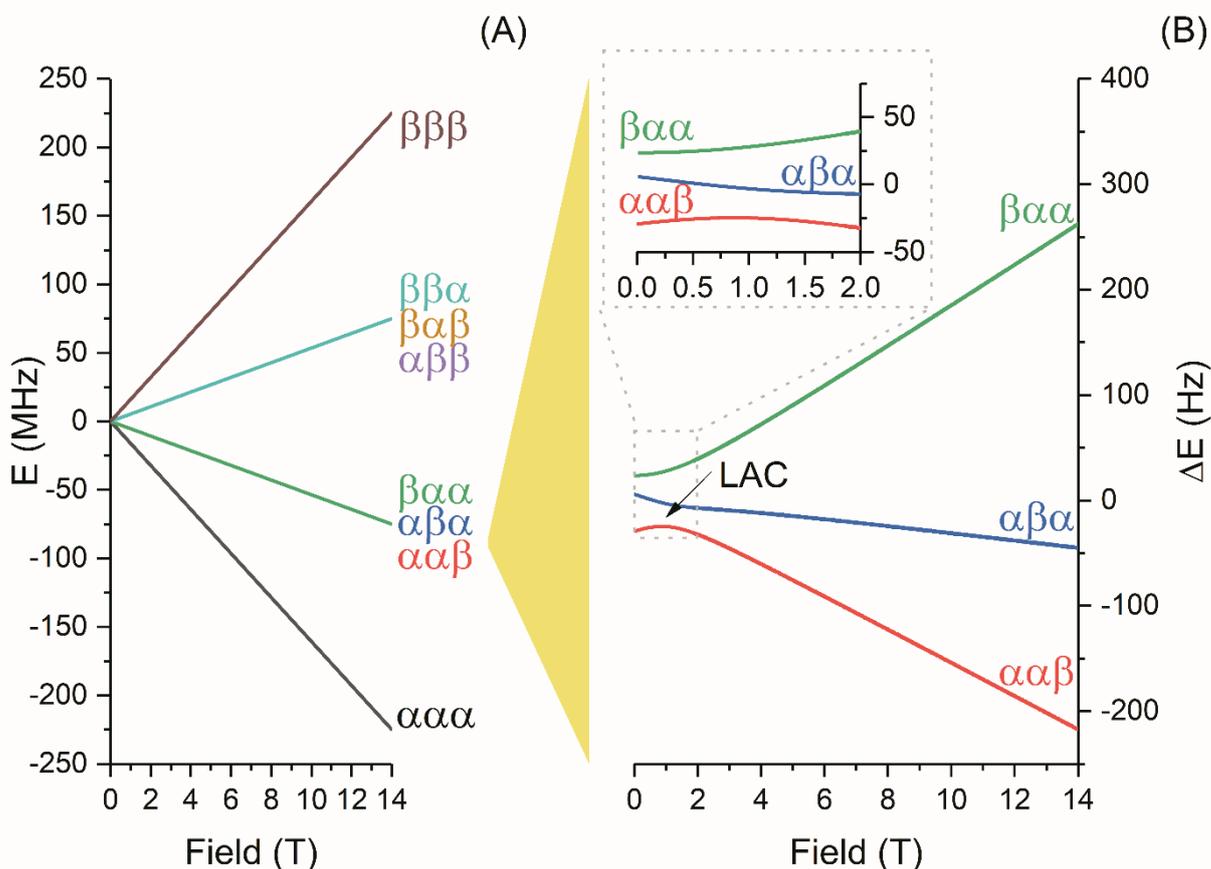

187 In the presence of scalar couplings to the third spin  $S$ , here a proton ( $I_1$  and  $I_2$  are carbon-13 nuclei), the  
188 expressions should be modified: the evolution should be calculated for each specific spin state of the  
189 proton,  $|\alpha\rangle$  and  $|\beta\rangle$ , and sum of the two curves should be taken. We obtain at the following expression:

$$\begin{aligned} \langle I_{1z} \rangle(t) &= 1 - \sin^2 \theta_+ \frac{1 - \cos[\omega_{ZQC}^+ t]}{4} - \sin^2 \theta_- \frac{1 - \cos[\omega_{ZQC}^- t]}{4} \\ \langle I_{2z} \rangle(t) &= \sin^2 \theta_+ \frac{1 - \cos[\omega_{ZQC}^+ t]}{4} + \sin^2 \theta_- \frac{1 - \cos[\omega_{ZQC}^- t]}{4} \end{aligned} \quad (7)$$

190 where the evolution frequencies are equal to  $\omega_{ZQC}^\pm = \sqrt{\Delta\omega_\pm^2 + (2\pi J_{12})^2}$ .

191 The time dependence of the expectation value for the longitudinal polarizations of spins  $I_1$  and  $I_2$  is  
192 presented in **Figure 3** in the presence and the absence of scalar couplings to a heteronucleus. In the  
193 absence of heteronuclear coupling the two strongly coupled spins (the strong coupling condition is  
194 fulfilled since  $2\pi J_{12} > \Delta\omega$ ) almost completely exchange polarizations. The polarization transfer is of a

195 coherent nature and the frequency of the oscillations is given by the scalar-coupling constant  $J_{12}$ . In the  
 196 presence of different heteronuclear scalar couplings to the third spin  $S$ , the time-evolution changes  
 197 considerably. The two spins are no longer in the regime of strong coupling, since  $|\Delta\omega_{\pm}| > 2\pi J_{12}$ . The  
 198 efficiency of polarization transfer is reduced and complete exchange of polarization is no longer possible.  
 199 The time dependence also becomes more complex: instead of a single frequency  $\omega_{ZQC}$  found in the  
 200 previous case, here two frequencies appear:  $\omega_{ZQC}^+$  and  $\omega_{ZQC}^-$ . Hence, when couplings to heteronuclei are  
 201 present, the condition  $\Delta\omega \sim 2\pi J_{12}$  does not guarantee that the homonuclei are in the strong-coupling  
 202 regime.

203  
 204 **Figure 4.** (A) Energy levels of the  $\{C^{\gamma}, C^{\delta 1}, C^{\delta 2}\}$  spin system at variable magnetic field strength in the absence of  
 205 scalar coupling with protons. Levels are assigned at high field, where the spin system is weakly coupled. (B) energy  
 206 levels, corresponding to the  $\alpha\alpha\beta$  and  $\alpha\beta\alpha$  states at high field, have a LAC at 1.1 T, which is responsible for generation  
 207 of the zero quantum coherences. To visualize the energy levels better, in the right panels we have subtracted the  
 208 large Zeeman energy from the actual energy and show the energy difference. The calculation is done using  
 209 parameters listed in [Table 1](#) and neglecting carbon-proton couplings.

210 These results show that the interaction with a heteronucleus clearly alters polarization transfer in strongly  
 211 coupled networks. Consequently, we expect strong effects of heteronuclear interactions on polarization  
 212 transfers in systems with several heteronuclei. Notably, we anticipate that polarization transfer among  
 213 strongly coupled carbon spins will be dramatically different in the presence of proton decoupling, which  
 214 effectively removes proton-carbon spin-spin interactions.

## 215 B. Spin dynamics simulations

216 In addition to this simple model, we carried out numerical simulations in a realistic multi-spin system: the  
 217 isopropyl group of carbon-13 labeled leucine. This spin system contains three carbon-13 nuclei  $I_1, I_2$ , and  
 218  $I_3$ : the  $C^{\gamma}$  carbon-13 and the two  $C^{\delta}$  carbon-13 nuclei. In addition, the spin system includes seven protons

219  $S_i$ : each  $C^{\delta}$  nucleus is coupled to the three protons of the methyl group, and the  $C^{\gamma}$  carbon-13 nucleus is  
 220 coupled to one proton. We model the effects of fast field variation and coherent spin dynamics at low  
 221 field. We consider two cases, namely, polarization transfer in the presence and in the absence of proton  
 222 decoupling.

223 The simulation method is as follows. The band-selective inversion pulse on spin  $I_3$  generates the initial  
 224 density operator for the three-spin  $I$  system:

$$\sigma_0 = \sigma(t = 0) = \hat{I}_{1z} + \hat{I}_{2z} - \hat{I}_{3z} \quad (8)$$

225 Hence, we generate a population difference for the states  $|\alpha\alpha\beta\rangle$ ,  $|\alpha\beta\alpha\rangle$  and  $|\beta\alpha\alpha\rangle$ : the first state is  
 226 overpopulated, while the other two states are underpopulated. The three-spin system under study,  $C^{\gamma}$ ,  
 227  $C^{\delta 1}$  and  $C^{\delta 2}$ , has a LAC at  $B = B_{LAC} \approx 1.1$  T, see Figure 4. Upon passage through a LAC during the field  
 228 jump  $B_{HF} \rightarrow B_{LF}$  due to the sample shuttle transfer, the population difference is expected to be  
 229 converted into a coherence between the states, which have the LAC: these adiabatic states correspond  
 230 to the  $|\alpha\alpha\beta\rangle$  and  $|\alpha\beta\alpha\rangle$  states at high fields. To calculate the actual spin state at  $B = B_{LF}$  we solve  
 231 numerically the Liouville-von Neumann equation for the spin density operator

$$\frac{d}{dt}\sigma = -i[\hat{\mathcal{H}}(t), \sigma] \quad (9)$$

232 The Hamiltonian of the spin system at a magnetic field  $B$  is as follows:

$$\begin{aligned} \hat{\mathcal{H}}(B) = & -\gamma_C B \sum_{i=1}^3 (1 + \delta_{Ci}) \hat{I}_{iz} - \gamma_H B \sum_{j=1}^7 (1 + \delta_{Hj}) \hat{S}_{jz} + 2\pi \sum_{i \neq k} J_{Cik} (\hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_k) \\ & + 2\pi \sum_{j \neq m} J_{Hjm} (\hat{\mathbf{S}}_j \cdot \hat{\mathbf{S}}_m) + 2\pi \sum_{i=1}^3 \sum_{j=1}^7 J'_{ij} \hat{I}_{iz} \hat{S}_{jz} \end{aligned} \quad (10)$$

233 Here  $\gamma_C$  and  $\gamma_H$  are the carbon and proton gyromagnetic ratios,  $\delta_{Ci}$  and  $\delta_{Hj}$  are the chemical shifts of the  
 234  $i$ -th carbon and  $j$ -th proton,  $J_{Cik}$  is the scalar coupling constant between the  $i$ -th and  $k$ -th carbon,  $J_{Hjm}$  is  
 235 the scalar coupling constant between the  $j$ -th and  $m$ -th proton,  $J'_{ij}$  is the scalar coupling constant between  
 236 the  $i$ -th carbon and  $j$ -th proton,  $\hat{\mathbf{I}}_i$  and  $\hat{\mathbf{S}}_j$  are the spin operator of the  $i$ -th carbon and  $j$ -th proton. Given  
 237 the range of magnetic fields considered here, heteronuclear scalar couplings are considered to be weak.

238 **Table 1.** Parameters used for energy calculations. Proton-carbon direct scalar coupling values marked by asterisk  
 239 have been used in numerical simulations of polarization transfer:

Chemical shifts	
$C^{\gamma}$	24.14 ppm
$C^{\delta 1}$	22.05 ppm
$C^{\delta 2}$	20.92 ppm
Scalar couplings	
$J(C^{\gamma} - C^{\delta 1})$	35 Hz
$J(C^{\gamma} - C^{\delta 2})$	35.4 Hz
$J(C^{\delta 1} - C^{\delta 2})$	0 Hz
$J(C^{\gamma} - H^{\gamma})^*$	127.4 Hz
$J(C^{\delta 1} - H^{\delta 1})^*$	124.8 Hz
$J(C^{\delta 2} - H^{\delta 2})^*$	124.8 Hz

240 The precise values of the calculation parameters are given in Table 1. Since the magnetic field  $B$  changes  
 241 with time, the Hamiltonian  $\hat{\mathcal{H}}$  is also time-dependent. In the calculation we consider three carbons and  
 242 seven protons (six protons in three  $CH_3$ -groups and the  $\gamma$ -proton). Using this Hamiltonian we evaluate the  
 243 density operator after the first field jump,  $\sigma(t = t_1)$ . The Liouville-von Neumann equation is integrated

244 using 1 ms time increments and assuming that for each step the Hamiltonian is constant, similarly to  
 245 simulations carried out for relaxation experiments (Bolik-Coulon et al., 2020). In the calculation, we ignore  
 246 relaxation effects, since the dimensionality of the relaxation superoperator is too big for the multi-spin  
 247 system considered here and our focus is on coherent effects.

248 At  $B = B_{LF}$  the density operator evolves under a constant Hamiltonian, at the end of the evolution period  
 249 it becomes as follows:

$$\sigma(t_1 + \tau) = \exp(-i\hat{\mathcal{H}}(B_{LF})\tau) \sigma(t_1) \exp(i\hat{\mathcal{H}}(B_{LF})\tau) \quad (11)$$

250 The  $B_{LF} \rightarrow B_{HF}$  field jump is simulated numerically in the same way as the first field jump (the time  
 251 interval is split into many small steps). Finally, knowing the density operator  $\sigma_{fin}$  at  $t = t_1 + \tau + t_2$ , we  
 252 evaluate the NMR signals of the nuclei of interest as the expectation values of their  $z$ -magnetization  
 253  $\langle I_{iz} \rangle = \text{Tr}\{\hat{I}_{iz}\sigma_{fin}\}$ .

254 The method used for modelling the experiments with decoupling at  $B = B_{LF}$  is different. After evaluating  
 255 the density operator  $\sigma(t = t_1)$  we trace out the proton degree of freedom and define the density  
 256 operator of the carbon subsystem as  $\sigma_C(t_1) = \text{Tr}_H\{\sigma(t_1)\}$ , with the argument that proton polarization is  
 257 destroyed by decoupling. The partial trace procedure implies that when  $\sigma_{ik,jl}$  is a proton-carbon density  
 258 operator (in the notation of spin states  $i, j$  stand for the proton states and  $k, l$  stand for the carbon states),  
 259 the elements of the carbon density operator are:  $\{\sigma_C\}_{k,l} = \sum_i \sigma_{ik,il}$ . One should note that proton two-  
 260 spin operators may contain a zero-quantum component, which would stand proton decoupling.  
 261 Consideration of effects of such coherences is beyond the scope of this work: we expect this to only lead  
 262 to small perturbations of the observed behavior. Then we introduce the Hamiltonian of the carbon  
 263 subsystem

$$\hat{\mathcal{H}}_C(B_{LF}) = -\gamma_C B_{LF} \sum_{i=1}^3 (1 + \delta_{Ci}) \hat{I}_{iz} + 2\pi \sum_{i \neq k} J_{Cik} (\hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_k) \quad (12)$$

264 Using this Hamiltonian, we evaluate the density operator of the  $^{13}\text{C}$  spins at the end of the evolution period  
 265 as follows

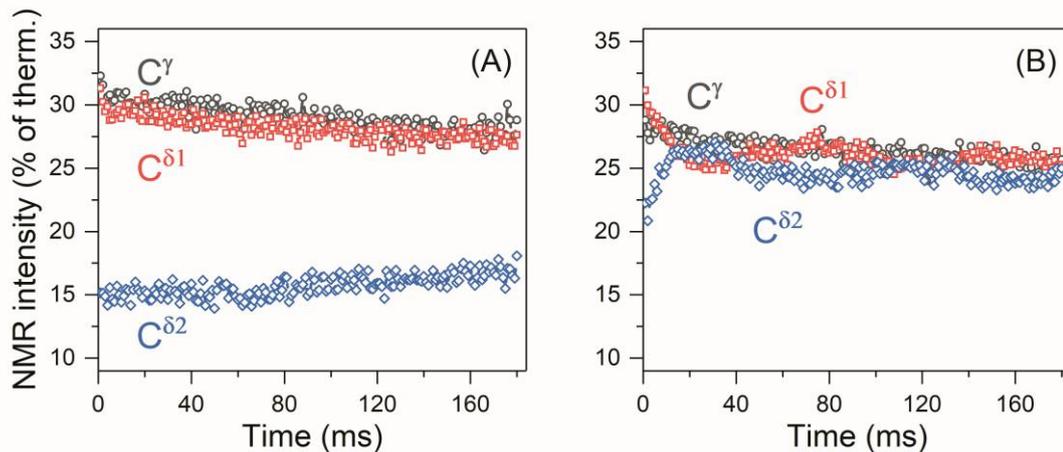

$$\sigma_C(t_1 + \tau) = \exp(-i\hat{\mathcal{H}}_C(B_{LF})\tau) \sigma_C(t_1) \exp(i\hat{\mathcal{H}}_C(B_{LF})\tau) \quad (13)$$

266 The final step in evaluating the ZQC evolution is introducing the carbon-proton density operator. This is  
 267 done by multiplying  $\sigma_C(t_1 + \tau)$  and the density operator of non-polarized protons (as decoupling removes  
 268 any proton spin order). Hence,

$$\sigma(t_1 + \tau) = \sigma_C(t_1 + \tau) \otimes \sigma_H^{dec}, \quad \sigma_H^{dec} = \frac{1}{2^7} \prod_{j=1}^7 \hat{1} \quad (14)$$

269 where  $\hat{1}$  is a  $2 \times 2$  unity matrix. The final step of the calculation, the field jump  $B_{LF} \rightarrow B_{HF}$ , is modelled  
 270 in the same way as in the previous case.

271 Finally, we would like to comment on the  $B(t)$  dependence, which was used in calculation. The distance  
 272 dependence of the magnetic field  $B(z)$  is precisely known but the precise  $z(t)$  is not known. We modelled  
 273 this dependence assuming that motion goes with a constant speed (in experiments, constant-speed  
 274 motion is achieved after a 5-10 ms lag delay for acceleration). Non-ideal agreement between theory and  
 275 experiment can be attributed to the fact that the precise  $z(t)$  dependence is not known (our previous  
 276 works (Pravdivtsev et al., 2013; Kiryutin et al., 2013) show that the knowledge of  $z(t)$  is required for  
 277 modeling).

278  
 279 **Figure 5.** Observed  $\tau$ -dependence of the polarizations of carbon-13 nuclei  $C^\gamma$ ,  $C^{\delta 1}$  and  $C^{\delta 2}$  measured **(A)** without  $^1\text{H}$   
 280 decoupling, and **(B)** with  $^1\text{H}$  decoupling. The NMR intensities are plotted in percent of the intensities of the NMR  
 281 signals in the 150.9 MHz  $^{13}\text{C}$  spectra (i.e., at 14.1 T) at thermal equilibrium.

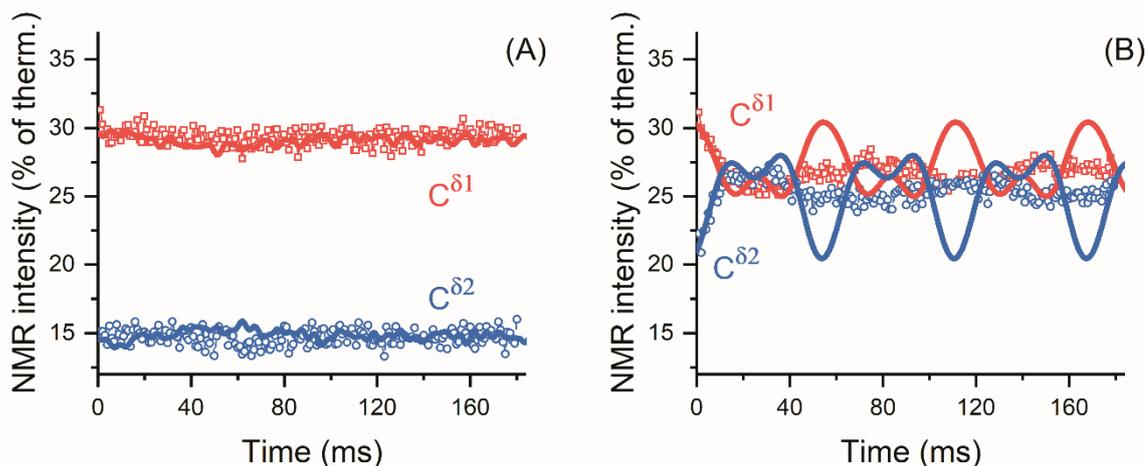

## 282 **IV. Results and discussion**

283 The experimental  $\tau$ -dependences of the measured spin polarization are shown in **Figure 5**. One can see  
 284 that without decoupling no coherent behavior is found: polarization simply decays due to relaxation and  
 285 no coherent oscillations are visible (**Figure 5A**). In the presence of proton decoupling (**Figure 5B**) the  
 286 situation is drastically different: coherent oscillations are clearly observed, which mediate polarization  
 287 exchange between the  $C^{\delta 1}$  and  $C^{\delta 2}$  nuclei. We attribute such polarization exchange to the ZQC, which is  
 288 generated by passage through the LAC. The coherence gives rise to exchange of the populations of the  
 289 two states, which experience the LAC. These levels are correlated with the  $|\alpha\alpha\beta\rangle$  and  $|\alpha\beta\alpha\rangle$  high-field  
 290 states. Hence, polarization transfer gives rise to population exchange of the states  $|\alpha\alpha\beta\rangle$  (initially  
 291 overpopulated state) and  $|\alpha\beta\alpha\rangle$  (initially underpopulated state). As a result, the state of the first spin,  $C^\gamma$ ,  
 292 does not change, but the other two spins,  $C^{\delta 1}$  and  $C^{\delta 2}$ , exchange polarizations. With the available speed  
 293 and range of the field-cycling, other coherences are not excited, i.e., non-adiabatic variation of the  
 294 Hamiltonian is achieved only for the pairs of levels that have the LAC in between  $B_{LF}$  and  $B_{HF}$ , i.e., only  
 295 the LAC shown in **Figure 4** contributes to spin mixing. The  $C^\gamma$  spin never shows any oscillatory polarization  
 296 transfer, which is an indication that the specific LAC is responsible for the observed effect. In conclusion,  
 297 a zero-quantum coherence of the two carbon-13 nuclei  $C^{\delta 1}$  and  $C^{\delta 2}$  is excited by fast magnetic field jump  
 298 between 14.1 T and 0.33 T.

299 Hence, the oscillatory behavior does not show up in the absence of proton decoupling. There are two  
 300 reasons for that. First, the multiple proton-carbon couplings give rise to a set of ZQC frequencies, instead  
 301 of a unique frequency in the presence of decoupling. Second and more importantly, proton-carbon-13  
 302 couplings prevent the carbon subsystem from reaching the strong-coupling regime. Thus, the amplitude  
 303 of coherent evolutions is drastically reduced (see Eq. 7) and becomes negligible (**Figure 5A**). As a result,  
 304 in experiments without decoupling the ZQC decays because of inhomogeneous broadening of the ZQC  
 305 evolution frequency, *i.e.* relaxation. We would like to stress that the ZQC of interest is excited by the field  
 306 jump, which is identical for experiments with and without proton decoupling at low field. However, the  
 307 ZQC does not reveal itself and does not give rise to efficient polarization transfer in the experiment  
 308 without decoupling.

309 These considerations are confirmed by theoretical modeling (**Figure 6**). In the presence of carbon-proton  
 310 couplings coherent oscillations are hardly observed: only fast oscillations of very small amplitude can be  
 311 seen in the simulated curves. By contrast, in the absence of the proton-carbon couplings, i.e., when  
 312 decoupling is used, coherent evolutions become manifest with slower oscillations of larger amplitude. The  
 313 results of numerical modeling are in good agreement with the experimental data. As relaxation effects

314 are not taken into account in simulations, to ease comparison we subtracted the slowly relaxing  
 315 background from the experimental time traces. In addition, we rescaled all calculated traces with the  
 316 same factor; then the starting polarization values were adjusted individually to achieve the best  
 317 agreement with the experimental data. Such a data treatment becomes necessary because relaxation is  
 318 active not only during spin mixing at the  $B_{LF}$  field, but also during the field jumps. The agreement between  
 319 the experimental data and simulation in **Figure 6** is not ideal, possibly because some small long-range  
 320 scalar couplings are not included in the simulation but most likely because the field switching profile is  
 321 not known exactly: previous studies of the spin dynamics in field-cycling NMR experiments (Pravdivtsev  
 322 et al., 2013; Kiryutin et al., 2013) suggest that using the precise  $B(t)$  profile is crucial for simulating  
 323 coherent polarization transfer phenomena.

324 **Figure 6.** Calculated  $\tau$ -dependence of polarization (lines) overlaid with the observed time traces (points) obtained  
 325 (A) without  $^1\text{H}$  decoupling, and (B) with  $^1\text{H}$  decoupling. The slowly relaxing background (compare with the data shown  
 326 in **Figure 5**) has been subtracted from the time traces, to enable comparison between theory and simulations.  
 327 Observed NMR intensities are normalized to intensities in 150.9 MHz (14.1 T)  $^{13}\text{C}$  spectra at thermal equilibrium. We  
 328 use the subtraction procedure because relaxation effects were not taken into account in the calculation;  
 329 consequently, we are unable to consider polarization decay due to relaxation at  $B_{LF}$  and during the field variation.  
 330 To enable comparison of the experiment and calculation results, the amplitude of oscillations in polarization transfer  
 331 traces were scaled with the same factor, then the starting polarization values were adjusted individually to give best  
 332 agreement with experimental data.  
 333

334 The absence of strong-coupling regime, in spite of scalar coupling constants larger than the difference in  
 335 Larmor frequencies is somewhat counterintuitive but clearly explained when taking into account the  
 336 effect of large heteronuclear scalar couplings (Eqs. 2-4). In the present case, the effect is even more  
 337 pronounced, since the two  $\delta$  carbon-13 nuclei of leucine are coupled to no less than 3 protons each,  
 338 further splitting resonance frequencies in the absence of proton decoupling. A conventional way to  
 339 present the weak coupling regime consists in stating that the part of the scalar coupling Hamiltonian (Eq.  
 340 1) that is proportional to a zero-quantum product operator is non-secular in the frame of the Zeeman  
 341 interactions of the two coupled spins, which is true if the scalar coupling constant is much smaller than  
 342 the difference in Larmor frequencies of the two spins. Here, the weak-coupling regime is extended  
 343 because this zero-quantum part can be considered non-secular in the interaction frame of the  
 344 heteronuclear scalar couplings (note that the perturbative treatment is allowed to the extent that the  
 345 heteronuclear coupling constants are much larger than the homonuclear coupling).

346 A particular consequence of the observation we report here can be relevant for experiments where the  
 347 strong scalar-coupling regime is created by radio-frequency irradiation: isotropic mixing for TOCSY  
 348 (Braunschweiler and Ernst, 1983). We have recently introduced a two-field TOCSY experiment where  
 349 isotropic mixing is carried out at 0.33 T and chemical shift evolutions occur at high field (Kadeřávek et al.,  
 350 2017), which makes broadband carbon-13 TOCSY straightforward. This study included a control

351 experiment where no radio-frequency pulses were applied at low field (see Figure 3.b in reference  
352 (Kadeřávek et al., 2017). Intuitively, one would have expected cross-peaks to be observed for carbon-13  
353 nuclei in strongly-coupled networks at 0.33 T. Some cross peaks could indeed be observed within the  
354 aliphatic carbon region of leucine and in the aromatic ring of phenylalanine. The current investigation  
355 suggests that strong scalar couplings between carbon-13 nuclei are less prevalent than expected at 0.33  
356 T. The observed cross-peaks were possibly due to cross-relaxation and not necessarily coherent evolution  
357 under strong scalar couplings. Conventional TOCSY experiments might also be altered by the effect of  
358 large heteronuclear scalar couplings. In this case, isotropic mixing sequences have been optimized on  
359 isolated pairs of two coupled spins (Kadkhodaie et al., 1991), excluding the effects of scalar couplings to  
360 heteronuclei or as heteronuclear decoupling sequences that happen to be efficient at isotropic mixing  
361 (Rucker and Shaka, 1989; Shaka et al., 1988). Although isotropic mixing sequences decouple heteronuclear  
362 scalar couplings, optimizing simultaneously for homo- and heteronuclear scalar coupling operators may  
363 improve homonuclear coherence transfers. Such effects of couplings to heteronuclei are of relevance for  
364 abundant nuclei (protons), whereas for other nuclei they become important when uniform spin labelling  
365 is used.

## 366 V. Conclusions

367 In this work, we present a study of coherent polarization transfer in a system of (strongly) coupled  $^{13}\text{C}$   
368 nuclei. Spin coherences are zero-quantum coherences, which are generated by a fast non-adiabatic  
369 magnetic field jump. Such coherences are excited most efficiently when the system goes through a LAC  
370 during the field switch. Here we indeed pass through a LAC in a system of three coupled  $^{13}\text{C}$  spins and  
371 investigate the spin dynamics at low fields, where strong couplings of the carbon spins are expected.

372 We can clearly demonstrate that the polarization transfer in the carbon-13 spin subsystem is strongly  
373 affected by spin-spin interactions with the protons in the molecule. In this situation, the role of these  
374 interactions can be determined by comparing the experiments with and without proton decoupling at low  
375 fields. When decoupling is used, we observe coherent polarization exchange between two of the three  
376 carbons: such a behavior is typical when the spin coherences are excited upon non-adiabatic passage  
377 through a specific LAC. In the absence of decoupling, i.e., when heteronuclear interactions are present,  
378 we cannot observe such a behavior: polarization transfer is very inefficient and coherent phenomena are  
379 not found. We attribute this to the fact that relatively strong proton-carbon couplings (i) drive the carbon  
380 system away from the strong coupling condition and (ii) give rise to a set of evolution frequencies instead  
381 of a unique ZQC frequency. These considerations are supported by an analytical model of a three-spin  
382 system and numerical simulations in a multi-spin system.

383 Our results are of importance for analyzing polarization transfer phenomena at low magnetic fields and  
384 for interpreting NMR data obtained under apparent strong coupling conditions. Under such conditions  
385 heteronuclear spin-spin interactions might disturb “strong coupling” of homonuclei and substantially alter  
386 spin dynamics. Similar effects also often arise in dynamic nuclear polarization, where the difference in the  
387 electron-nuclear couplings for nuclei located at different distances from the electron hampers nuclear  
388 spin diffusion, giving rise to the spin diffusion barrier around the electron spin (Ramanathan, 2008).
