Abstract

Exact Nuclear Overhauser Enhancement (eNOE) yields highly accurate, ensemble averaged 1H - 1H distance restraints with an accuracy of up to 0.1 Å for the multi-state structure determination of proteins as well as for Nuclear Magnetic Resonance Molecular Replacement (NMR^2) to determine the structure of the protein-ligand interaction site in a time-efficient manner. However, in the latter application, the acquired eNOEs lack the obtainable precision of 0.1 Å because of the asymmetrical nature of the filtered NOESY experiment used in NMR^2 . This error is further propagated to the eNOE equations used to fit for and extract the distance restraints.

In this work, a new analysis method is proposed to obtain inter-molecular distance restraints from the filtered NOESY spectrum more accurately and intuitively by dividing the NOE cross-peak by the corresponding diagonal peak of the ligand. The method termed diagonal-normalized eNOEs was tested on the data acquired by Torres et al. (Torres et al., 2020) on the complex of PIN1 and a small, weak-binding phenylimidazole fragment. NMR^2 calculations performed using the distances derived from diagonal-normalised eNOEs yielded the right orientation of the fragment in the binding pocket, and produced a structure that more closely resembles the benchmark X-ray structure (2XP6) (Potter et al., 2010) with an average heavy atom RMSD of 1.681 Å with respect to it, when compared to the one produced with traditional NMR^2 with an average heavy atom RMSD of 3.628 Å. This is attributed to the higher precision of the evaluated distance restraints.

19 1 INTRODUCTION

20 Nuclear Magnetic Resonance Molecular Replacement (NMR²) is a hybrid approach to determine the structure
 21 of protein-ligand complexes, utilising a previously determined structure (for example, a X-ray structure or
 22 a structure from a protein homolog) of the target protein and combining it with the spatial information
 23 extracted by solution state NMR to identify the binding pocket of the protein and the orientation of the ligand
 24 inside it (Wälti and Orts, 2018). The major strength of the method is that one does not need to carry out
 25 protein resonance assignment to obtain the complex structure. Using NMR², Orts et al. has been able to solve
 26 the structure of various complexes (Torres et al., 2020); (Wälti and Orts, 2018); (Orts et al., 2016) accurately
 27 (up to 1 Å) within a few days of measurement and analysis. The NMR² structure calculation workflow is
 28 detailed in (Orts and Riek, 2020) and relies on acquiring precise inter-molecular distance restraints.

29 In NMR², the ¹³C, ¹⁵N-labelled protein and non-labelled ligand are mixed and measured together using
 30 the F₁-[¹⁵N, ¹³C]-filtered [¹H, ¹H]-NOESY experiment (Zwahlen et al., 1997) to extract the inter-molecular
 31 NOE rates and the corresponding distances. This analysis is performed in an in-built module within CYANA
 32 structure calculation software (Güntert and Buchner, 2015) called ENORA (Strotz et al., 2017). ENORA fits
 33 the NOE buildup curves obtained at multiple mixing times to extract exact cross-relaxation rates (eNOEs)
 34 which produces semi-accurate distance restraints with both upper and lower limit (Vögeli et al., 2009).

35 However, the precision of these inter-molecular distance restraints is much lower (~20% higher tolerance
 36 needed) (Strotz et al., 2015) than the bi-directional intra-molecular eNOEs, usually measured inside the
 37 protein, from a series of ¹⁵N, ¹³C-resolved [¹H, ¹H]-NOESY experiments that have a precision of 0.1 Å. The
 38 lower precision is attributed to the imbalanced magnetisation pathway within the F₁-¹⁵N, ¹³C-filtered [¹H, ¹H]-
 39 NOESY experiment, the lack of a clean steady state magnetisation at the beginning of the experiment, the
 40 unknown spin diffusion contribution (Kalk and Berendsen, 1976) and the complexity involved in extracting
 41 distances within ENORA, which further propagates errors arising from the NOESY spectrum.

42 In this work, we present an alternative approach for extracting cross-relaxation rates from the filtered
 43 2D NOESY spectra that forgoes the need for the sophisticated and time-intensive eNORA calculations and
 44 produces more accurate distances. The complex used in this study is that of cis/trans isomerase PIN₁ with
 45 a low molecular weight fragment, 2-(3-Chlorophenyl)-5-methyl-1H-imidazole-4-carboxylic acid, drawn in
 46 Figure A1, whose structure of the interaction site was solved by Torres et. al (Torres et al., 2020), in order to
 47 test the NMR² method for weak binding small molecules. This fragment called Compound 2 in the paper
 48 by Torres et al. (Torres et al., 2020) produces very few inter-molecular eNOEs to PIN₁, due to its small size
 49 (comprising only a few protons) and low binding affinity (760 μM). This makes the de-novo determination
 50 of the right pose of the ligand in the binding pocket using NMR² very challenging.

51 As we shall see, our approach has been successful in producing better restraints for the PIN₁-Compound
 52 2 complex than the standard procedure thereby predicting the right orientation of the ligand in the binding
 53 pocket when compared with the X-ray structure of this complex (2XP6) (Potter et al., 2010), which serves as
 54 a benchmark to ascertain the accuracy of the NMR² structures.

55 2 THEORY

56 Following the standard NMR theory of the NOESY experiment (Keepers and James, 1984), the proposed
 57 analysis arises out of simple approximations made on the fundamental equations used to calculate eNOEs.
 58 Every spin pair that produces a cross-peak can be assumed to form a two-spin system. The cross-relaxation
 59 rate for a two-spin system (i and j) can be analytically given as (Macura et al., 1986); (Boelens et al., 1988);
 60 (Vögeli, 2014):

$$\frac{I_{ij}(t)}{I_{ii}(0)} = \frac{I_{ji}(t)}{I_{jj}(0)} = \frac{-\sigma_{ij}}{\lambda_+ - \lambda_-} (\exp\{-\lambda_- t\} - \exp\{-\lambda_+ t\}) \quad (1)$$

61 where $I_{ii}(t)$ and $I_{ij}(t)$ represent the peak intensity of the diagonal and the cross-peak in the NOESY
 62 spectrum respectively. The cross-relaxation rate, σ_{ij} , further depends on λ_{\pm} which are a function of auto-
 63 relaxation rates of the two spins, ρ_i and ρ_j .

$$\lambda_{\pm} = \frac{\rho_i + \rho_j}{2} \pm \sqrt{\left(\frac{\rho_i - \rho_j}{2}\right)^2 + \sigma_{ij}^2} \quad (2)$$

The diagonal intensities can be approximated by a single-exponential decay, completely independent of the auto- and cross-relaxation rates of the other spin:

$$I_{ii}(t) = I_{ii}(0) \exp\{-\rho_i t\} \quad (3)$$

64 Furthermore, under the assumption that $\rho_i \approx \rho_j = \rho$, which holds true for small- to medium-sized proteins,
 65 the exponential terms in Equation 1 can be expanded to the second-order as follows:

$$\exp\{-\lambda_{\pm} t\} = \exp\{-(\rho \pm \sigma)t\} = 1 - (\rho \pm \sigma)t + \frac{(\rho \pm \sigma)^2 t^2}{4} \dots \quad (4)$$

Combining Equations 1, 3 and 4, the following expression can be obtained:

$$\boxed{\frac{I_{ij}(t)}{I_{ii}(t)} = -\sigma_{ij} t} \quad (5)$$

66 This straightforward expression relates the cross-peak and diagonal intensities at mixing time, t , to the
 67 cross-relaxation rate. These quantities can be directly extracted from NOESY spectra recorded at multiple
 68 mixing times and fitted with a simple linear model to compute the cross-relaxation rate. This forgoes the
 69 need for invoking the ENORA module to fit the NOE build-ups. More importantly, it produces more accurate
 70 rates as it only involves directly fitting the experimentally-derived peak build-up intensities once. With the
 71 standard approach used in ENORA, the diagonal intensities are fitted in accordance with Equation 3 to
 72 extrapolate the auto-relaxation rate, ρ_i and the initial magnetisation, $I_{ii}(0)$. The error introduced to these
 73 quantities by imprecise fitting of Equation 3 and low SNR of diagonal peaks is propagated to Equations 1 and
 74 2, which are used to determine σ_{ij} . Furthermore, the imbalance inherent to the F_1 - $[^{15}\text{N}, ^{13}\text{C}]$ -filtered $[^1\text{H}, ^1\text{H}]$ -
 75 NOESY experiment and the missing ρ_i contributes to the relative error. This error is also compounded in the
 76 eNORA approach as the peak intensity data is transformed and used in multiple fitting equations.

77 The rates determined with the new method proposed here using Equation 5 are termed diagonal-
 78 normalised NOEs. The conversion from the obtained cross-relaxation rates to distances can be made via the
 79 equations reported in the previous NMR² publications (Wälti and Orts, 2018). Please note that in the case of
 80 PIN1-Compound 2 complex, the effective correlation time used to convert rates to distances was derived
 81 from steric distances found in the fragment (Torres et al., 2020).

82 However, there is a level of uncertainty still attached to the distance restraints extracted via this method
 83 because of the assumption, $\rho_i = \rho_j$, especially for large ligand-protein complexes with weak binding affinities,
 84 as ρ_j might be an order of magnitude above ρ_i . A simple test was performed to quantify the uncertainty
 85 introduced by the above assumption to the extracted distances. It involved taking artificial distances (3 Å and
 86 5 Å) between spin pairs followed by back calculating the value of the respective cross-relaxation rates. The
 87 obtained rates were fed to Equations 1 and 2 with varying assumptions of the values of the auto-relaxation
 88 rates (ρ_j and ρ_i). The ratios of magnetisation transfer $\frac{I_{ij}(t)}{I_{ii}(t)}$ were obtained at identical mixing times [40, 60, 90
 89 and 120 ms], as used by Torres et al. (Torres et al., 2020) and fitted according to the Equation 5 in an attempt
 90 to reproduce the artificial distances.

91 The results of the test are detailed in Figure A2 in the Appendix. At the ratio of $\frac{\rho_j}{\rho_i} = 10$, the highest
 92 measured ratio, generally expected for the complex of a large protein and a small ligand, our method was

93 able to reproduce the inter-molecular distance with an accuracy of 12.45% for both 3 Å and 5 Å. Hence, we
 94 propose a distance accuracy of $\pm \sim 10\%$ for our approach. This distance accuracy lies between distances
 95 derived from bi-directional eNOEs (0%) and uni-directional eNOEs (20%) (Strotz et al., 2015). It is noted that
 96 the software CYANA uses a harmonic potential for its target function (TF) to accommodate the distance
 97 restraints, and as such 0% means that only harmonic potential is involved, whereas 20% distance tolerance
 98 indicates the presence of a flat potential from 0%-20% distance followed by the harmonic potential beyond it
 99 (Güntert and Buchner, 2015).

100 3 RESULTS AND DISCUSSION

101 In order to evaluate the accuracy of the distance extraction method of diagonal-normalised NOEs the
 102 PIN₁-Compound 2 complex introduced above is used. All the NMR experiments on the PIN₁-Compound 2
 103 complex were conducted and the subsequent resonance assignments were performed by Torres et al (Torres
 104 et al., 2020) (co-authors in this study). They resolved the structure of the binding pocket using NMR² on
 105 the inter-molecular, uni-directional, eNOE-derived distance restraints which have an expected accuracy of
 106 20% (Strotz et al., 2015). In this work, we have used their data, recorded on ¹⁵N,¹³C-filtered [¹H,¹H]-NOESY
 107 spectra, to evaluate the performance of the diagonal-normalised eNOE analysis as compared to the the
 108 standard eNOE approach (Vögeli et al., 2009); (Vögeli, 2014).

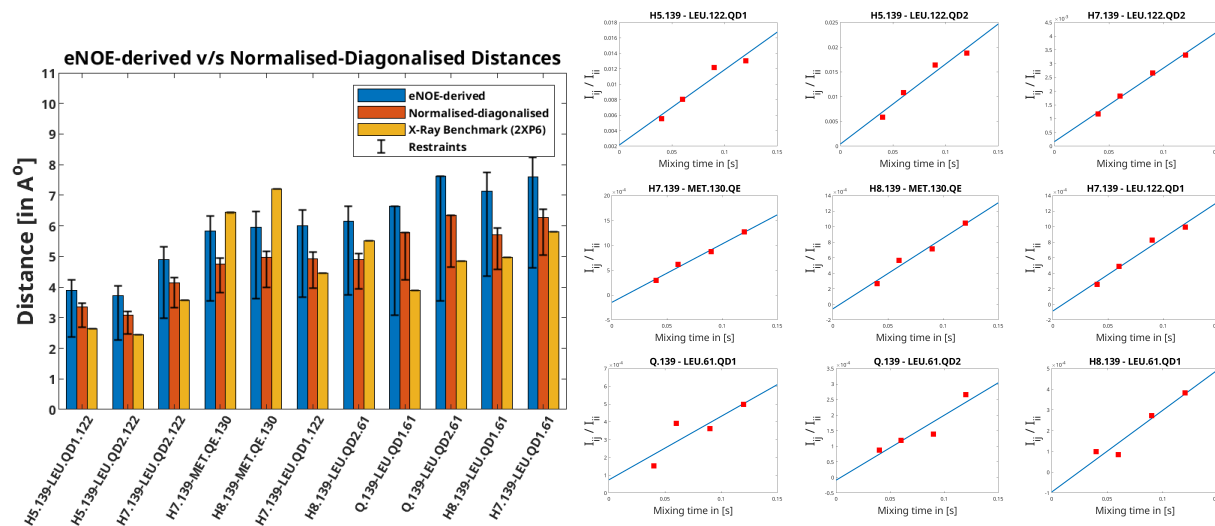

Figure 1: (Left) Distances extracted from F₁-[¹⁵N,¹³C]-filtered [¹H,¹H]-NOESY using the eNOE (blue) and diagonal-normalised approach (red) compared to the benchmark X-ray structure. The bars denote the distances that arise from the cross-relaxation rates from the complex of PIN₁ with Compound 2, as given in (Torres et al., 2020). The bars in yellow represent the distances back-calculated from the X-ray structure (2XP6) (Potter et al., 2010). The error bars denote the upper and lower limit restraints produced in CYANA (Güntert and Buchner, 2015) for the extracted distances. A tolerance of 20% and 10% was taken and for the eNOE and the diagonal-normalised approach extracted distances respectively. (Right) The ratio of NOE buildups to the corresponding diagonal peak intensities plotted against mixing time for the PIN₁-Compound 2 complex for the diagonal-normalised approach. The data points were fitted using a linear least square fitting model in MATLAB (MATLAB, 2018). The slope denotes the cross-relaxation rate of the given peak, as per Equation 5.

109 Apart from being more time-efficient and intuitive, this method should also provide more accurate
 110 distances, as discussed in the Theory section. The NOE build ups plots, fit linearly according to Equation
 111 5, are depicted in Figure 1 (right). The linear fits mostly tend to zero when mixing time is zero and the

112 experimental data fits well even at longer mixing times for all cross-peaks. This indicates a lack of significant
 113 spin diffusion contribution. Moreover, it is easier to detect spin diffusion with this method compared to the
 114 standard approach using eNORA, as it manifests itself as non-linearity in the fitted data. This difference is
 115 illustrated in Figure A3 in the Appendix.

116 The derived distance restraints are also plotted against the conventional eNOE-derived distance restraint
 117 and the distances back-calculated from the benchmark X-ray structure (2XP6) (Potter et al., 2010) in Figure 1
 118 (left) (The protons were added to the X-ray structure in CYANA (Güntert and Buchner, 2015)). Indeed, the
 119 diagonal-normalised distance restraints better resemble the ones from the X-ray structure (mean difference
 120 in the distances being $1.04 \pm 0.65 \text{ \AA}$) than the ones from the standard approach (mean difference in the
 121 distances being $1.57 \pm 0.73 \text{ \AA}$). The only exceptions being the distances that include the protons from the
 122 solvent-exposed Methionine 130.

123 The inter-molecular distances obtained from the PIN1-Compound 2 complex through the conventional
 124 eNORA-based method and the diagonal-normalised approach are plotted in Figure 1. The plots illustrate
 125 that the restraints obtained via the latter are tighter by $0.4\text{-}1.2 \text{ \AA}$. The source of this difference, as discussed
 126 in the Theory section, arises from the inherent complexity involved in extracting distances from a filtered
 127 2D-NOESY spectrum.

128 To evaluate the 10% error estimate deduced in the Theory section further and to study the impact of the
 129 diagonal-normalised distance restraints on NMR² structure determination, NMR² structures of the complex
 130 PIN1-Compound 2 were calculated with varying degree of precision of the diagonal-normalised distance
 131 restraints (i.e. 0%, 5%, 10%, and 20%) (Table 1). The restraints were input in the NMR² algorithm and the
 132 output structures were compared to the structure determined in (Torres et al., 2020) using standard eNOEs.

133 The NMR² program screens all potential combinations of methyl groups in protein and protons on the
 134 ligand and calculates the complex structure for all of the possibilities without needing protein assignment.
 135 The success of an NMR² run lies in it being able to discriminate between all the possible structures and
 136 pinpoint the right pose of ligand in the binding pocket. This is especially difficult for small fragments like
 137 Compound 2, with only 5 distinct protons/methyl groups.

Table 1: Table detailing the results of NMR² calculations with distance restraints extracted from eNOE and diagonal-normalised method with varying values of errUni in CYANA.

Method Used	Precision (in % of the given distance) ¹	Does the structure converge up to TF = 2 Å ² ? (Yes/No) ²	Target Function of 4 lowest energy conformers (in Å ²)	Total number of degenerate lowest energy conformers ³	RMSD w.r.t to the benchmark (2XP6) (in Å ²)
eNORA-based	20%	Yes	[0, 0, 0, 0]	10+	3.63
Diagonal-Normalised	20%	Yes	[0, 0, 0, 0]	5	2.17
Diagonal-Normalised	10%	Yes	[0.03,0.12,0.20,0.73]	1	1.68
Diagonal-Normalised	≤ 5%	No	–	–	–

¹A precision of x% dictates the value of upper limit and lower limit distance restraints with the upper limit distance restraint being $(1+x\%)*(\text{extracted distance})$ and the lower limit distance restraint being $(1-x\%)*(\text{extracted distance})$.

² A target function (TF) of less than 2 Å² within NMR² is considered a successful structure determination (Orts and Riek, 2020).

³ The total number of degenerate lowest energy conformers is the number of distinct orientations of the ligand within the binding pocket that were obtained with a CYANA target function (TF) of 0 Å² from NMR² calculations.

Figure 2: Surface representation of the binding pocket of PIN1 with Compound 2 from two different perspectives. Coloured in cyan is the surface representation of the protein alongside a stick representation of ligand determined by X-ray crystallography studies (2XP6) (Potter et al., 2010). Coloured in brown is the stick representation of the structure of the ligand inside the binding pocket determined by Torres et al. (Torres et al., 2020) with a distance precision of 20% using the standard ENORA approach. Coloured in purple is the structure determined by NMR^2 calculations using the distances extracted via the diagonal-normalised approach with a precision of 10% (refer to Row 3 in Table 1). The nitrogen, oxygen and chlorine atoms on the ligand are coloured blue, red and green respectively.

138 Table 1 outlines the details of the structure calculation test. The restraints obtained through the eNORA-
 139 based method were not good enough and gave rise to more than 10 degenerate structures with a Target

140 Function (TF) of 0 \AA^2 , meaning that all experimental distance restraints were fulfilled without inconsis-
141 tency/error in any of the 10 degenerate structures. The structure in which the ligand has the same orientation
142 inside the binding pocket, as the benchmark X-ray structure (2XP6) (Potter et al., 2010), has an RMSD of
143 3.63 \AA with respect to the X-ray structure (2XP6). Using the diagonal-normalised distance determination
144 procedure with a precision of 20%, a better performance is observed with only 5 degenerate structures with a
145 TF of 0 \AA^2 , which included the complex structure with Compound 2 in the right pose (RMSD of 2.17 \AA). For
146 the anticipated precision of the distance restraints of 10%, the calculation produced only one structure with
147 a TF = 0.03 \AA^2 , coloured in purple in Figure 2, which shows the same orientation as the crystal structure
148 with an RMSD of 1.68 \AA . This structure superimposes well with the benchmark structure, coloured in cyan
149 in Figure 2. A visual inspection of the binding pocket illustrated in Figure 2 shows that the ligand appears
150 deeper in the binding pocket and better aligned with the crystal structure compared to the structure obtained
151 by traditional, eNORA-based NMR². For a distance precision of 5% and below, the calculations did not
152 converge to structures that fulfil the experimental restraints and produce structures below the hard limit of
153 TF < 20 \AA^2 . This is expected since the distance restraints are not of the quality of bidirectional restraints due
154 to the assumption $\rho_i = \rho_j$, the lack of spin diffusion correction and other restrictions inherent to the NMR²
155 protocol, such as the use of a previously determined protein structure and combining X-ray and NMR data.

156 The strength of this approach lies in distinguishing the correct pose of a weak-binding, low molecular
157 weight ligands which gives very few inter-molecular NOEs inside the binding pocket of a larger proteins.
158 Nevertheless, this approach was also tested on the protein-ligand complex of HDM2, a human oncogenic
159 protein, with caylin-1, which presents abundant inter-molecular NOEs. The traditional eNORA-based NMR²
160 was successful in characterising the structure of protein-ligand interaction site (7QDQ), as shown in the work
161 of Mertens et al. (Mertens et al., 2022). With the diagonal-normalised approach at 10% precision, we obtained
162 the same pose of caylin-1 in the HDM2 binding site, as Mertens et al., with a TF of 1.52 \AA^2 and RMSD
163 between the two structures being 0.81 \AA (refer to Figure A4 in the Appendix). Furthermore, the calculations
164 made with 15% and 20% precision also matched the predictions of traditional NMR² in identifying the right
165 structure. This is further evidence that our approach can at least match the predictions of traditional NMR²
166 in the case of strong binders and possibly exceed them in the case of weak binders with less NOEs. It is
167 noted that the presence of multiple configurations/conformations of the ligand in the binding pocket will
168 require detailed eNOE-based multi-state structure calculations (Vögeli et al., 2013); (Ashkinadze et al., 2022).

169 To sum up, this work proposes an intuitive and time-efficient, alternative method to extract precise
170 distance restraints from a series of filtered-NOESY spectra, that gives, in the system studied, an accurate
171 NMR² structure of the protein-ligand interaction site.

172 4 MATERIALS AND METHOD

173 No new material was prepared for the sake of this work. The protocol to express and purify the protein and
174 the ligand and to mix them afterwards is detailed in (Torres et al., 2020).

175 No new NMR experiments were conducted for this work either. The peak intensities from the spectra
176 acquired by Torres et al. were extracted via ccpNMR (Skinner et al., 2016). The intensities were later fit to
177 acquire the rates in the MATLAB Software suite (MATLAB, 2018). The structure calculation were performed
178 by NMR² program through CYANA (Güntert and Buchner, 2015). All the structures were displayed and
179 overlaid over each other using the Chimera molecular visualisation tool (Pettersen et al., 2004).

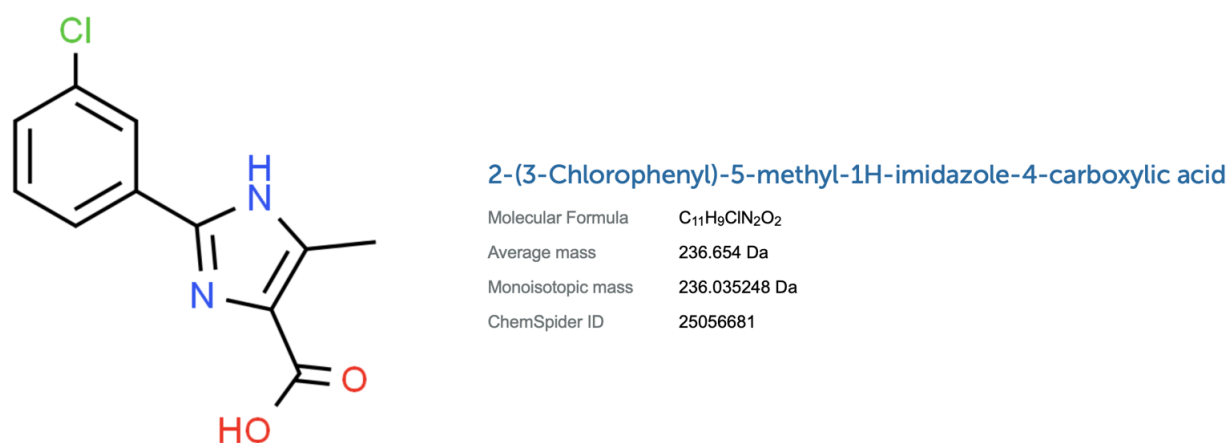

Figure A1: A line representation of Compound 2 (2-(3-Chlorophenyl)-5-methyl-1H-imidazole-4-carboxylic acid) from (Torres et al., 2020). The figure was obtained from ChemSpider (ID:25056681).

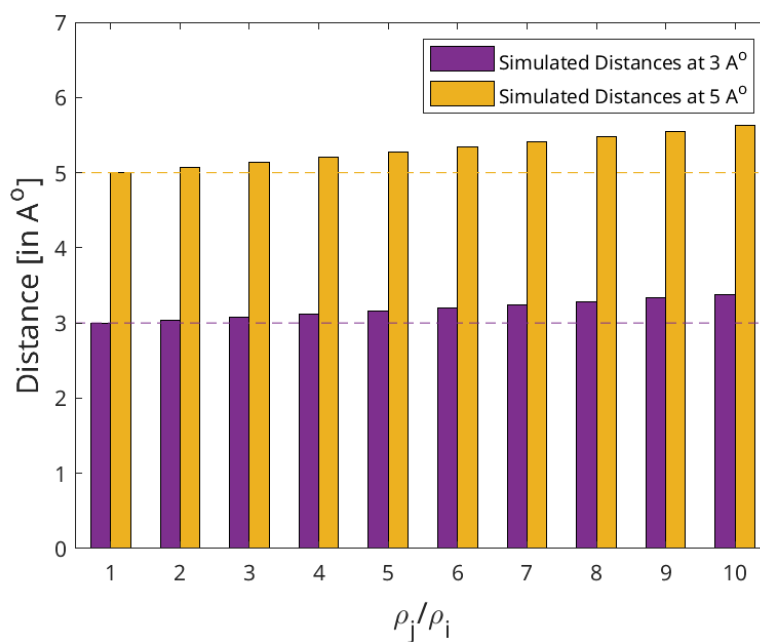

Figure A2: The effect of the relative auto-relaxation rates of the protein and the ligand on the distances extracted via the diagonal-normalised approach. The dotted lines represent the artificial distances 3 Å and 5 Å in purple and yellow respectively. The corresponding bars denote the distances back-calculated using the diagonal-normalised approach from the artificial distances depending on the relative auto-relaxation rates, ρ_i and ρ_j . Each set of distances (bars) are derived through varying assumptions of the values of ρ_i and ρ_j with respect to each other ranging from $\frac{\rho_j}{\rho_i} = [1 \text{ to } 10]$.

Figure A3: Effect of spin diffusion on the intensity build-up curves produced from eNORA-based approach (left) and diagonal-normalised approach (right). The build-up curves were fitted using artificially simulated peak intensities in a model system, Third Immunoglobulin Binding Domain of Protein G (GB3), which has been extensively studied using eNOE spectroscopy (Vögeli et al., 2012); (Vögeli et al., 2013). The blue curve represents the intensity build-up in an isolated two-spin system with an inter-proton distance of 3.83\AA and the red curve represents the same two spins experiencing spin-diffusion due to presence of other spins in the system. The comparison between the plots highlight that it is easier to detect the influence of spin-diffusion with the diagonal-normalised approach (right), as it induces deviation from the expected linear fit.

Figure A4: Ribbon representation of the protein, HDM2, with the stick representation of caylin-1 present in the binding pocket. Coloured in brown is the surface of the structure determined by traditional NMR^2 (7QDQ) by Mertens et al. (Mertens et al., 2022). Coloured in green is the structure determined by NMR^2 calculations using the the diagonal-normalised approach with a precision of 10%. The nitrogen and oxygen atoms on the ligand are coloured blue and red respectively.
